Single-crystal diamond cavity optomechanical devices are a promising example of a hybrid quantum system: by coupling mechanical resonances to both light and electron spins, they can enable new ways for photons to control solid-state qubits. However, realizing cavity optomechanical devices from high-quality diamond chips has been an outstanding challenge. Here, we demonstrate single-crystal diamond cavity optomechanical devices that can enable photon–phonon spin coupling. Cavity optomechanical coupling to 2 GHz frequency ($f_m$) mechanical resonances is observed. In room-temperature ambient conditions, these resonances have a record combination of low dissipation (mechanical quality factor, $Q_m > 9000$) and high frequency, with $Q_m \cdot f_m \sim 1.9 \times 10^{13}$, which is sufficient for room-temperature single-phonon coherence. The system exhibits high optical quality factor ($Q_o > 10^4$) resonances at infrared and visible wavelengths, is nearly sideband resolved, and exhibits optomechanical cooperativity $C \sim 3$. The devices’ potential for optomechanical control of diamond electron spins is demonstrated through radiation pressure excitation of mechanical self-oscillations whose 31 pm amplitude is predicted to provide 0.6 MHz coupling rates to diamond nitrogen vacancy center ground-state transitions ($6\, \text{Hz/phonon}$) and $\sim 10^5$ stronger coupling rates to excited-state transitions.

1. INTRODUCTION

Diamond optomechanics are an attractive platform for controlling the interactions between light, vibrations, and electrons that underlie future hybrid quantum technologies [1]. Their potential arises from diamond’s exceptional mechanical and optical properties [2], combined with its ability to host color centers such as the nitrogen-vacancy (NV), whose electron spins are excellent qubits that can be manipulated by local mechanical strain fields [3–7]. Recently, the piezoelectric actuation of bulk [3,8] and nanomechanical [4–7,9–11] diamond resonators has been used to demonstrate phononic spin control. Cavity optomechanics [12] harness optical forces in place of piezoelectric actuation, allowing coherent phonon state manipulation [13–15] of GHz frequency mechanical resonators with quantum limited sensitivity [16]. These phonons can be made resonant with NV center electron spin transitions that are central to proposals for spin–spin entanglement [17], spin-phonon state transfer [18–20], spin-mediated mechanical normal mode cooling [17,21,22], and photon–phonon spin coupling [23]. Additionally, the relatively small thermal occupancy and mechanical dissipation of GHz diamond devices, combined with diamond’s ability to support strong optical fields due to its large electronic bandgap, make them an ideal system for the cavity optomechanical backaction cooling and study of mechanical resonators in their quantum ground state [16].

The development of cavity optomechanical devices from single-crystal diamond has been limited due to the challenges associated with fabricating mechanically isolated structures from bulk diamond chips. While the initial development of diamond optomechanical devices used nanocrystalline diamonds [24], a single-crystal diamond material promises lower mechanical dissipation [25] and the ability to host highly coherent NV centers [26]. Here, we report the demonstration of a single-crystal diamond cavity optomechanical system for the first time. This system is based on a microdisk device geometry that has been used in a wide range of cavity optomechanics experiments implemented in more conventional semiconductor and dielectric materials [13,15,27,28]. Microdisks are desirable owing to their simple geometry, strong optomechanical coupling between high-frequency mechanical resonances and low-loss optical modes, and intrinsic ability to simultaneously support optical modes over the entire transparency window of the device material [15].

The microdisk system studied here, an example of which is shown in Fig. 1(a), supports optical modes at visible and telecommunication wavelengths ($\omega/2\pi \sim 200–470\, \text{THz}$) that interact...
via radiation pressure with GHz frequency mesoscopic mechanical resonances of the structure. We find that these resonances have a record combination of high $\omega_m$ and low mechanical dissipation ($\gamma_m = \omega_m/Q_m \sim 2\pi \times 0.2$ MHz) compared to other mechanical resonators operating in ambient temperature and pressure, and that their $Q_m \cdot f_m = 1.9 \times 10^{13}$ Hz product is sufficiently high to satisfy the minimum criteria for single-phonon coherent behavior [12]. The microdisk optical modes have low dissipation ($\gamma_o = \omega_o/Q_o \sim 3 \times 3$ GHz), and owing to the negligible non-linear absorption in diamond at telecom optical frequencies, they can support an intracavity photon number $N > 10^6$ without degrading $Q_o$. In combination, this allows for the realization of optomechanical cooperativity, $C = N \gamma_m \gamma_o/\gamma_m \sim 3$, large enough (>1) for coherent photon–phonon coupling [13,14], where $g_0 \sim 2\pi \times 26$ kHz is the single photon optomechanical coupling rate of the device and describes the expected shift in the cavity optical frequency due to the mechanical zero-point motion of the microdisk. These devices operate on the border of the sideband-resolved regime ($Q_o \sim \omega_m$), enabling radiation pressure backaction excitation of mechanical self-oscillations with ~31 pm amplitude. The accompanying stress fields are strong enough to drive diamond color center spin transitions with a single phonon-spin coupling that is predicted to exceed that of previously studied monod color center spin transitions with a single phonon-spin coupling [5–7], despite having orders of magnitude higher $\omega_m$ and smaller phonon amplitude, owing to the localized nature of the microdisk mechanical resonances. In addition, the ability of the microdisks to support optical modes at visible wavelengths is compatible with resonant optical frequency due to the mechanical zero-point motion of the microdisk. These devices operate on the border of the sideband-resolved regime ($Q_o \sim \omega_m$), enabling radiation pressure backaction excitation of mechanical self-oscillations with ~31 pm amplitude. The accompanying stress fields are strong enough to drive diamond color center spin transitions with a single phonon-spin coupling that is predicted to exceed that of previously studied monod color center spin transitions with a single phonon-spin coupling [5–7], despite having orders of magnitude higher $\omega_m$ and smaller phonon amplitude, owing to the localized nature of the microdisk mechanical resonances. In addition, the ability of the microdisks to support optical modes at visible wavelengths is compatible with resonant

2. FABRICATION OF SINGLE-CRYSTAL DIAMOND MICRODISKS

There has been significant recent progress in the fabrication of mechanically isolated single-crystal diamond devices, including demonstrations of suspended high-$Q_o$ nanomechanical resonators [4,25,30–32] and high-$Q_o$ micro- and nanocavities [33,34]. These structures have been created using diamond membrane thinning [25,30,35], plasma angled etching [33], and plasma undercutting [32,34] fabrication techniques, with the latter two approaches allowing for the patterning of devices from bulk diamond chips. Here, we use plasma undercutting to fabricate single-crystal diamond cavity optomechanical devices [32,34]. These devices were fabricated from an optical grade, chemical vapor deposition (CVD)-grown (100)-oriented single-crystal diamond substrate supplied by Element Six. The polished substrates were first cleaned in boiling piranha and coated with ~400 nm of plasma-enhanced chemical vapor deposition (PECVD) $\text{Si}_3\text{N}_4$ as a hard mask. To avoid charging effects during electron beam lithography (EBL), ~5 nm of Ti was deposited on the $\text{Si}_3\text{N}_4$ layer before coating the sample with a ZEP 520A EBL resist. The developed pattern was transferred to the hard mask via inductively coupled plasma reactive-ion etching (ICPRIE) with $\text{C}_4\text{F}_8$/SF$_6$ chemistry. The remaining EBL resist was removed with a 6 min deep-UV exposure (5 mW/cm$^2$ at 254 nm), followed by a 2 min soak in Remover PG, while the remaining Ti was removed by the subsequent etch steps. The anisotropic ICPRIE diamond etch was performed using O$_2$, followed by the deposition of ~250 nm of conformal PECVD $\text{Si}_3\text{N}_4$ as a sidewall protection layer. The bottom of the etch windows were then cleared of $\text{Si}_3\text{N}_4$ using a short ICPRIE $\text{C}_4\text{F}_8$/SF$_6$ etch. This was followed by a zero RF power O$_2$ RIE diamond undercut etch to partially release the devices. Lastly, the $\text{Si}_3\text{N}_4$ layer was removed using a wet etch in 49% HF, and the devices were cleaned again in boiling piranha. The devices studied here have diameters of 5.0 to 6.0 $\mu$m and an average thickness ~940 nm. As evident from the image in Fig. 1(a), the devices are fabricated with a process optimized to minimize the waist of the pedestal supporting the microdisk, reducing it to <100 nm, where the waist is defined as the smallest point of the pedestal. The microdisk thickness, which will be reduced in future work to enhance confinement, is determined by the interplay between the inward and upward etch rates of the quasi-isotropic undercut, together with the initial anisotropic etch depth. The undercut time was chosen to optimize the pedestal waists of the ~5 $\mu$m diameter microdisks studied here. A longer undercut would allow the study of larger diameter microdisks (from 6 to 8 $\mu$m) present on the chip, which would in turn possess a smaller thickness than the structures studied here.

3. DEVICE CHARACTERIZATION

A. OPTICAL CHARACTERIZATION

The devices were characterized by monitoring the transmission of a dimpled optical fiber taper [36,37] evanescently coupled to the

Fig. 1. Characterization of diamond microdisk optical and mechanical modes at low optical input power. (a) SEM image of a 5 $\mu$m diameter microdisk, with minimum pedestal width of 100 nm. Inset: Simulated displacement distribution of the RBM mechanical resonance of this device. (b) Highest $Q_o$ TM-like optical modes of a 5 $\mu$m (left) and 5.5 $\mu$m (right) diameter microdisk, with intrinsic quality factors for each doublet resonances, as labeled. (c) High-$Q_o$ visible mode with intrinsic quality factor, as shown for a 6.2 $\mu$m diameter microdisk. (d) $S_p(f)$ produced by the thermal motion of the RBM of the microdisks in (b), showing that the larger diameter, larger pedestal waist microdisk has a lower $Q_m$. 

Vol. 3, No. 9 / September 2016 / Optica 964
microdisk and input with light from tunable diode lasers (New Focus Velocity) with wavelengths near 1530 or 637 nm. For the 1530 nm measurements, the output of the fiber taper was monitored by both low- and high-bandwidth photodetectors (Newport 1621 and 1554-B, respectively) and a calibrated optical power meter (Newport 2936-R). Figure 1(b) shows typical \( T(\lambda) \) when the fiber taper is evanescently coupled to devices with diameters of 5.0 and 5.5 \( \mu \)m and the wavelength \( \lambda \) of the 1530 nm tunable laser is scanned across microdisk modes at \( \lambda_o \). Here, \( T \) is the average transmission measured by the low-bandwidth photodetector over a timescale that is long compared to 1/\( f_m \). These measurements reveal resonant coupling to modes with loaded \( Q_o \sim 5.8 \times 10^4 \)–6.0 \( \times \) \( 10^4 \) (intrinsic \( Q_o \)) = 6.1 \( \times \) \( 10^3 \)–6.8 \( \times \) \( 10^4 \)) and a degree of doublet structure that depends on the internal parameters of 5.0 and 5.5 \( \mu \)m when the fiber taper is evanescently coupled to devices with diameters of 2000 nm. The hourglass shape of the pedestals obtained for the (100) optical-grade diamond samples used here limits the minimum size of the pedestal where it connects to the microdisk and may result in increased dissipation. Given the crystal plane selective nature of the diamond undercut [34], fabricating microdisks from samples with alternate crystal orientations such as (111) may alleviate this limitation. Additionally, an operation in a vacuum, where viscous air damping can be avoided [40, 41], and at low temperature [25, 32] would allow a decrease in dissipation, as the total \( Q_m \) is given by \( Q_m = (\sum 1/Q_m)^{-1} \), where \( Q_m \) represents the quality factor due to each damping mechanism. Despite the present limitations, the demonstrated devices have \( Q_o \cdot f_m = 1.9 \times 10^{13} \) Hz, which is larger than all previously studied cavity optomechanical systems operating in ambient conditions [28, 39, 42]. A comparison of some of the highest \( Q_m \cdot f_m \) products for optomechanical systems observed in ambient, cryogenic, and low-pressure environments is shown in Supplement 1, Section 3. This figure of merit is critical for cavity optomechanical mass spectroscopy [27, 43, 44] and low phase noise oscillators [45]. Within the context of quantum optomechanics, this product satisfies a key minimum requirement for room-temperature studies of single-phonon coherence by over an order of magnitude: \( \omega_n/\gamma_m \gg n_{th} \), where \( n_{th} \) is the room temperature phonon population of the RBM, ensuring that thermal decoherence is slow compared to a mechanical oscillation [12]. By satisfying this condition, cooling to the quantum ground state from room temperature should also be possible [46].

To investigate the response of the cavity optomechanical transduction, \( S_P \) was monitored while \( \lambda_o \) was scanned across \( \lambda_o \). Figure 2(a) shows the resulting measurement of \( S_P(f, \lambda_o) \) for the microdisk in Fig. 1(a), clearly illustrating that optomechanical transduction is only observable when \( \lambda_o \) is tuned in the vicinity of \( \lambda_o \). In this measurement, the EDFA was connected to the input side of the fiber taper, resulting in maximum \( N \sim 10^4 \) and \( P_d \sim 1.5 \) mW, where \( P_d \) is the optical power dropped into the microdisk mode. From the thermo-optic coefficient of diamond, we estimate that the shift of 400 nm from the cold cavity \( \lambda_o \), as seen in Figure 2(a), corresponds to a change in device temperature \( \Delta T \sim 50 \) K. The COMSOL simulations that take into account the reduced thermal conductivity coefficient of the \( \sim 100 \) nm diameter pedestal compared to bulk [47] confirm that an absorbed power of \( \sim 10\% \) of \( P_d \) reproduces the temperature shift observed here (see Supplement 1, Section 1). Although this temperature increase is not desirable for quantum optomechanics applications, it is considerably smaller than the expected increase for a similar Si device. Assuming a similar absorption rate and identical device geometry, a silicon device with a silicon or silicon dioxide pedestal would result in \( \Delta T \sim 200 \) K or 450 K, respectively, where a modified thermal conductivity also applies to the silicon in the pedestal [48]. It is expected that the rate of linear absorption observed here, which corresponds to \( Q_o \) = 6.2 \( \times \) \( 10^5 \), can be reduced through improvements in processing, B. CAVITY OPTOMECHANICAL COUPLING

To probe optomechanical coupling within the microdisks, time \( (t) \)-dependent transmission fluctuations \( 6\Delta T(t, \lambda) \) of 1550 nm light were monitored using a real-time spectrum analyzer (Tektronix RSA5106A). Excitations of the microdisk mechanical resonances modulate \( \lambda_o \), resulting in a dispersive optomechanical transduction of mechanical motion to an optical signal \( P_o \Delta T(t, \lambda_o) \) that can then be observed in the measured electronic power spectrum \( S_P(f) \). Here, \( P_o \) is the average power transmitted to the photodetector. Figure 1(d) shows typical spectra when \( \lambda_o \) is tuned near the point of maximum transduction of the modes in Fig. 1(b). Resonances near \( f_m \sim 2.0\)–2.1 GHz are observed, corresponding to optomechanical transduction of the thermomechanical motion of the fundamental radial breathing mode (RBM) of the microdisks. The predicted displacement of the RBM calculated using finite element simulations (COMSOL) is shown in the inset of Fig. 1(a). The simulated \( f_m \) of the RBM for varying microdisk diameters was found to be within 10% of the observed values. These measurements were conducted at a low input power \( P_I \sim 50 \) \( \mu \)W to avoid the optomechanical backaction effects discussed below. Here, an erbium-doped fiber amplifier (EDFA: Pritel LNHPFA-30) was used on the output side of the fiber taper to boost the optical signal prior to photodetection to a level just below the detector saturation power (\( P_s \approx 0.7 \) mW).

The microdisk pedestal can significantly affect the RBM properties, and minimizing its waist size is important in order to maximize \( Q_m \) and reach \( C > 1 \). In previously studied diamond microdisks with \( \mu \)m pedestal waists [34], the transduction of mechanical modes was not observed. As shown in Fig. 1(a), the devices used here for cavity optomechanics have significantly smaller waists, e.g., the 5.0 \( \mu \)m diameter microdisks have waist <100 nm. Figure 1(d) shows that when the microdisk diameters, and as a result, the pedestal waist are increased to 5.5 \( \mu \)m and 400 nm, respectively, \( Q_m \) is found to decrease from \( \sim 9000 \) to \( \sim 2000 \). Mechanical resonances are not observed in devices with a pedestal diameter >500 nm. This indicates that \( Q_m \) for these devices is limited by clamping loss [28, 39].
accounting for the dependence of $\omega_0$ on $N$ due to the thermo-optic effect. For a given operating $\omega_m$, $\omega_0$ was predicted from $N$ (see Supplement 1, Section 1), where $N(\omega_0)$ was determined from $\mathcal{F}(\omega_0)$, $P_f$, $Q^{(0)}_s$ and measurements of loss through the fiber taper and other elements of the apparatus.

To quantitatively investigate the role of radiation pressure on the mechanical resonance dynamics, the observed $\delta \gamma_m(\Delta)$ was fitted to the expected cavity optomechanical damping rate [12], with the single-photon optomechanical coupling rate $g_0$ as the only free parameter. Using this method, the fit shown in Fig. 2(b) was obtained for $g_0/2\pi \sim 26$ kHz, with an associated 95% confidence interval of $\pm 2$ kHz. The errors bars for each $\delta \gamma_m$ data point in Fig. 2(b) represent the 95% confidence interval of fits used to extract $\gamma_m$ from $S_p$. The large uncertainty as well as the discrepancy between the measured and predicted values when $\Delta \sim 0$ or $\gg \gamma_0$ are due to the low signal to noise of $S_p$ in these regions. This low signal to noise of $S_p$ also prohibited measuring the optomechanical response for $\Delta \gg \gamma_0$. The fitted value for $g_0$ has good agreement with the value of $g_0$ predicted from the COMSOL calculations, which include both moving boundary (MB) and photoelastic (PE) contributions [50]. The predicted $g_0$ is dependent on the spatial overlap of the optical field and mechanical displacement profile, which varies for each optical mode. We find that the fitted value of $g_0$ most closely agrees with the predicted coupling rate of the second-order radial TM-like mode, with $g_{0MB}/2\pi = 18$ to 24 kHz and $g_{0PE}/2\pi = 16$ kHz. In comparison, $g_{0MB}/2\pi = 17$ kHz (19 kHz) and $g_{0PE}/2\pi = 29$ to 36 kHz ($\sim 24$ to $26$ kHz) for the fundamental TM (TE) mode of the microdisk. This is consistent with the measurements of the mode polarization in the fiber taper, which indicated that the microdisk mode studied here is TM polarized. Note that the stated uncertainty in the predicted $g_{0MB}$ is due to variations in the reported PE coefficients of single-crystal diamond [51].

Figure 2(c) shows a similar analysis of $\delta \omega_m(\Delta)$, indicating that $\omega_m$ is softened by over 300 kHz by the intracavity field. This shift is due to both optomechanical dynamical backaction and static thermal effects. For the operating regime and devices used here, the dynamic thermal effects are expected to be below 5% of the optomechanical radiation pressure dynamical backaction effects and can be neglected [42]. However, the static thermal effects are significant. Heating of the microdisk for a large $P_f$ results in both thermal expansion and a change in Young's modulus, resulting in a shift to $\omega_m$ [52–54]. This effect is linear in $P_f$, assuming that $Q_o$ is independent of power, i.e., the nonlinear absorption is small. To compare the measured $\delta \omega_m(\Delta)$ with the theory, we used a model that includes radiation pressure-induced optomechanical dynamic backaction [12] and a static heating term linearly proportional to $P_d$:

$$\delta \omega_m(\Delta) = g_0^2 N \left( \frac{\Delta - \omega_m}{\gamma_0^2/4 + (\Delta - \omega_m)^2} + \frac{\Delta + \omega_m}{\gamma_0^2/4 + (\Delta + \omega_m)^2} \right) + \alpha P_d \tag{1}$$

The resulting fit of Eq. (1) to the measured $\delta \omega_m$ is shown in Fig. 2(c) to have a close agreement. Notably, this model reproduces the kink in $\delta \omega_m(\Delta)$, where the amplitude of the optomechanical contribution reaches a maximum and changes signs. This fit was obtained with $g_0$ fixed to the value extracted from the analysis of $\delta \gamma_m$ in Fig. 2(b) and with $\alpha$ as a fitting parameter.

At higher powers, the microdisk optomechanical dynamics can be dramatically modified. Figure 3 shows the behavior of the...
The potential of these devices for hybrid spin-optomechanics applications can be measured by the predicted strain coupling rate $g_e$ between a single phonon of the microdisk RBM and a single-diamond NV center electron spin. The maximum zero-point motion strain of the RBM is $\varepsilon_{zpm} \approx 3 \times 10^{-10}$, and we estimate $g_e / 2\pi = d\varepsilon_{zpm} \approx 6$ Hz for a negatively charged NV$^-$ center.
electron spin optimally located 50 nm below the top surface of the device in Fig. 3(c), exceeding the highest rate demonstrated to date [7]. Here, \( \Delta \approx 10-20 \) GHz is the strain susceptibility of the ground-state spin [5,6]. When the RBM is self-oscillating, as in Fig. 3(c), the predicted coupling rate is \( G/2\pi \approx 0.6 \) MHz [5]. This is comparable to coupling rates achieved in piezoelectric actuated nanomechanical [5–7] and bulk devices [3,8]. The longest room-temperature ground-state spin decoherence time (\( T_2 \)) observed to date in an isotopically engineered single-crystal diamond is 1.8 ms [26], while typical \( T_2 \) values in nanostructures are on the order of 100 \( \mu \)s [5,56]. Additionally, dynamical decoupling schemes can be utilized to extend this time, as \( T_2 \sim 600 \) ms has been observed at low temperatures [57]. Phonon-spin control should be possible provided \( G/2\pi > T_2 \), which is the case for these devices.

The GHz frequency of the RBM enables low room-temperature phonon occupation, relevant for cooling to the quantum ground state from room temperature [16]. This also enables access to larger energy spin transitions [3,8] than were possible using the previously demonstrated diamond nanomechanical resonators. This may be particularly important for future studies of phonon coupling to the NV\(^-\) center excited-state manifold, which could achieve single-phonon coupling rates close to MHz due to the \( \sim 10^5 \) times larger strain susceptibility of the excited states [10,22,58,59]. This is promising for implementing fully quantum photon–phonon–spin interfaces and for proposals of the spin-mediated cooling of nanomechanical resonators [17,21,22].

In the samples under study, we expect to find NVs optimally coupled to the RBM since the nitrogen concentration for this diamond sample (\( \sim 10^5 \) ppm, corresponding to a number density of \( 1.76 \times 10^{13} \) m\(^{-3} \)) results in high-concentration NV ensembles. However, future studies with higher purity samples may require NV implantation to optimally locate NVs \( \sim 50 \) nm below the device surface. Additionally, due to the minimal coupling of fluorescence from an NV center located at the center of the microdisk to the optical modes, free space collection would most likely be required. However, the use of higher-order radial breathing modes could allow for greater spatial overlap of the strain and electromagnetic field maxima [60], allowing for more efficient fiber-based excitation and collection.

Future improvements of \( Q_0 \) to values above \( 10^5 \) and approaching \( 10^6 \) should be possible [33,34], thus enabling ultralow self-oscillation threshold [55] and operation deep in the sideband-resolved regime required for optomechanical ground-state cooling [16]. Operating in a vacuum, at a low temperature, and using devices fabricated from high-purity electronic-grade diamonds may allow further increases in \( Q_m \) [25], boosting the achievable photon–phonon cooperativity \( C \) and \( Q_m \cdot f_m \) product. Similarly, reducing the microdisk diameter may increase \( C \) through enhanced \( g_0 \) while also increasing \( \omega_m \). Simulations predict that diameters close to 3.5 \( \mu \)m are possible before radiation loss limits \( Q_o < 10^3 \); such devices would have \( g_0/2\pi > 95 \) kHz and \( f_m \sim 3.4 \) GHz. Finally, using electronic-grade diamond materials and investigating processing techniques to reduce surface-state absorption may decrease optical absorption and allow larger \( N \) before device heating becomes significant.

5. Conclusion

In conclusion, we have shown that cavity optomechanical devices can be realized from single-crystal diamond, with record high ambient condition optomechanical cooperativity, \( C \sim 3 \), and a \( Q_m \cdot f_m \) product of \( 1.9 \times 10^{13} \). These devices are a promising testbed for ambient-condition coherent optomechanics experiments, e.g., ground-state cooling [16], optomechanically induced transparency [13–15], and phonon-mediated wavelength conversion [15,61,62], as well as studies in quantum information science [63], and hybrid quantum systems involving light, phonons, and diamond NV center spins [3,5–7,17,21,23]. We have also shown that the microdisks demonstrated here support high-\( Q_o \) optical modes at wavelengths near resonance with the 637 nm optical transition of NV centers, further enhancing their potential for photon–phonon spin coupling experiments.

We note that, in parallel to this work, Burek et al. have demonstrated cavity optomechanics in single-crystal diamond optomechanical crystals fabricated by a Faraday cage angled-etching technique [64].
